(Received May 25, 2004; Revised November 19, 2004; Accepted December 1, 2004)

Following the Hyogoken Nanbu earthquake (January 17, 1995, Mw=7.2), three drillholes were sunk through the Nojima Fault (Awaji Island, Japan). Textural and petrographic studies of the Geological Survey of Japan (GSJ) drill cores allow recognition of two deformation episodes. The first one is older than the deposition of the Middle to Late Eocene Kobe Group, corresponds to a left-lateral movement on the Nojima fault and is expressed by pseudotachylytes, kinking of biotite crystals in the low-strain rocks and an intense laumontite hydrothermal alteration. The second one displaces the basal unconformity of the Kobe group, corresponds to a right-lateral reverse displacement and is expressed at least by carbonate-filled hydraulic fractures and thin gouge zones. Different important deformation mechanisms are recorded by the fault rocks, but questions relating to the attribution of deformation and alteration features to one or other deformation episodes remain unresolved.

Key words: Nojima, fault, seismic, aseismic, deformation, veins, laumontite, carbonates.

1. Introduction

The Nojima fault (Awaji Island, Japan) has been extensively studied after the Hyogo-ken Nanbu earthquake (January 17, 1995, Mw=7.2). Three drill holes (drilled by GSJ, NIED and University group) have encountered the fault at different depths and have allowed structural observations of the fault imprint on the surrounding rocks. This paper summarizes the results of a textural and petrographic study of the drill cores from the GSJ borehole, and points out the different important mechanisms recorded by the fault rocks and some unresolved questions.

2. The Geodynamic Context of the Nojima Fault

The Nojima fault has a N45°E orientation and a subvertical dip (85°SE). Left-lateral transcurrent faults with identical N45°E orientation were formed in southwest Japan during the Late Cretaceous-Palaeocene (Kanaori, 1990) and are interpreted to belong to a fault network defining a regional block structure. Reactivation of these faults occurred in pre-5 Ma times (left-lateral) and in Late Pliocene to Quaternary times (right-lateral) (Fig. 1; Fabbri *et al.*, 2004).

In the Awaji Island (Fig. 2), the Nojima fault cross-cuts the Cretaceous Nojima granodiorite (K-Ar ages on miner-

als ranging from 70 to 90 Ma, Takahashi, 1992; cooling age at 74±3 Ma by zircon fission track method, Murakami and Tagami, 2004) and its porphyry dykes. The granodiorite is unconformably overlain by the Kobe Group, the base of which has been dated to Middle to Late Eocene (Yamamoto *et al.*, 2000), and by the Plio-Pleistocene Osaka Group (Murata *et al.*, 2001). The Quaternary vertical offset is 490 to 540 m as determined by the vertical displacement of the Kobe Group basal unconformity (Murata *et al.*, 2001). The corresponding average slip rate (0.4–0.5 m/10³ years down-dip and 0.9–1.0 m/10³ years right-lateral) of the Nojima fault has been estimated by Mizuno *et al.* (1990).

Studies of deformation and alteration textures indicate that the fault damage zone is >46.5 m wide and the fault core itself is 30 cm wide (Ohtani *et al.*, 2000, 2001; Tanaka *et al.*, 2001; Fujimoto *et al.*, 2001). However, if the Nojima fault has followed the same two-stage evolution of the N45°E fault system, the present-day thickness of the fault is the result of deformation accumulated over its whole history and it is important to understand what are the deformation and alteration structures related to each episode. In order to decipher this two-stage history, it should be pointed out that deformation structures related to the recent activity of the fault could not have formed at a depth greater than the present-day depth of the sample within the drill hole plus the Quaternary 490–540 m vertical offset. Conversely, any structure formed at a depth greater than the present-day

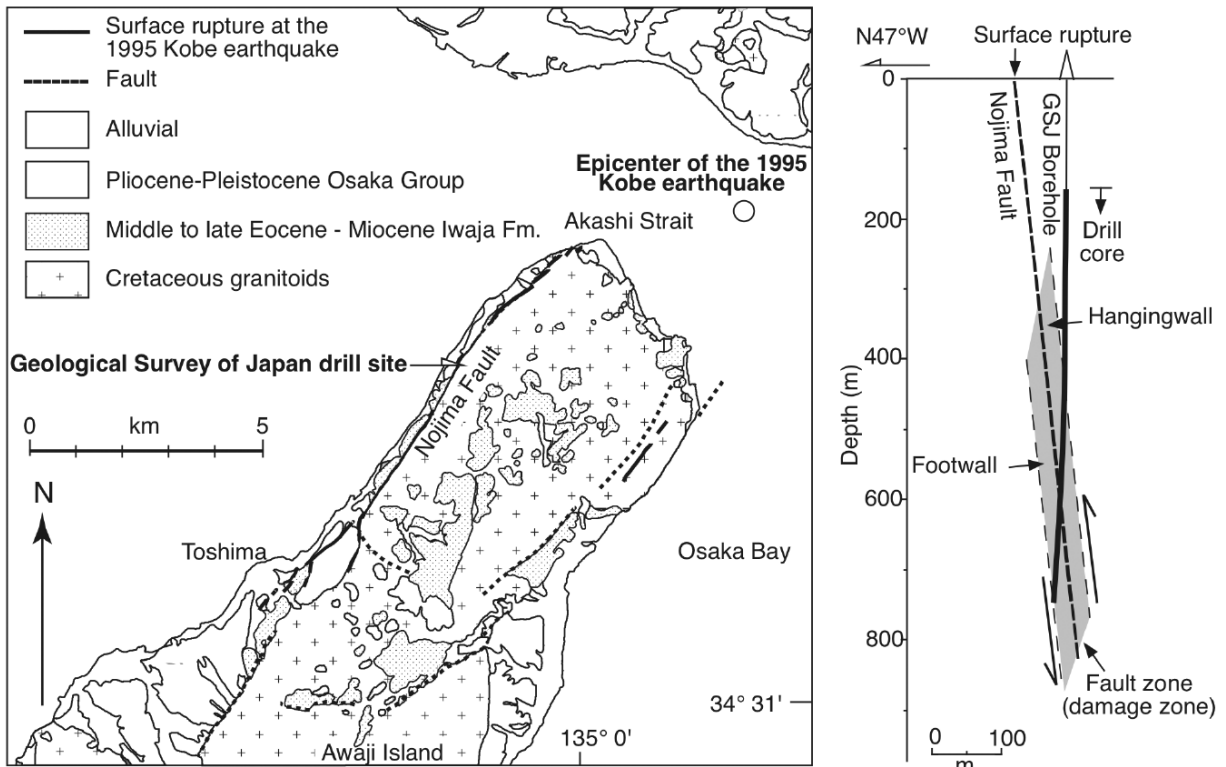

Fig. 2. Geological map of the Awaji Island and sketch of the Hirabayashi borehole showing the relative orientations of the fault and borehole (after Ohtani *et al.*, 2000). The shaded pattern on the sketch represents the fault zone (i.e. damage zone).

Fig. 3. Microphotograph of shortened cleavages in biotite in an oriented horizontal thin section at 352 m depth. North is indicated by the thick black line. Note also the black trace of a fracture acting as a dissolution or stylolite-like plane.

Orientations of kinked (001) planes in biotites

Fig. 4. Histogram of the orientation of shortened biotite cleavage planes relative to the North in the thin section shown in Fig. 3 at 352 m depth. Two maxima are observed at N15E and N100E respectively.

depth of the sample within the drill hole plus the Quaternary 490–540 m vertical offset should have been formed before the displacement of the Kobe Group basal unconformity.

3. Microstructural Studies of the Fault Rocks

3.1 Low strain rocks

Outside the fault zone, the granodiorite may appear as undeformed. However, careful observations indicate that some strain is recorded in these rocks. Two directions of horizontal shortening are observed in the Nojima granodiorite in the GSJ borehole. They can be deduced from the orientation of fluid inclusion planes (mode I cracks), and kink-bands in quartz and biotite (Fig. 3). Following Boullier *et al.* (2000), the first shortening event recorded by kinked cleavage planes in biotites (Fig. 4) is NNW-SSE orientated and coincides with the principal orientation of fluid inclusion planes (Takeshita and Yagi, 2000), and with cracks sealed by albite and chlorite. Consequently, they probably appeared in greenschist facies conditions (around 300°C). Takeshita and Yagi (2000) suggest that this first shortening event, which is consistent with a left-lateral movement on the N45°E Nojima fault, occurred in Late Cretaceous times (around 85 Ma) just after the solidification of the granodiorite.

3.2 Pseudotachylytes

Pseudotachylytes are observed in the fault core (Ohtani *et al.*, 2000, 2001; Tanaka *et al.*, 2001; Boullier *et al.*, 2001; Otsuki *et al.*, 2003). They are closely related to some fine-grained fault gouges (Otsuki *et al.*, 2003), which are characterized by an isotropic or homogeneous texture without any strain localization (no shear plane), and have experienced fluidization (Otsuki *et al.*, 2003).

Boullier *et al.* (2001) described fluid inclusions within pseudotachylytic glass in the fault core at 624.59 m in the GSJ drill hole. The fluid inclusions are filled with a high density H₂O+CO₂ fluid. Isochoric lines calculated from these fluid inclusions (Fig. 5) indicate that they were formed at a minimum depth of 15 km for a 24°C/km geothermal gradient (Kitajima *et al.*, 1998; Yamaguchi *et al.*, 1999) or 10 km if a slightly higher 30°/km geothermal gradient is chosen. Consequently, the pseudotachylytes which con-

Fig. 5. Isochoric lines calculated from the microthermometric data on fluid inclusions in pseudotachylytes, after Boullier *et al.* (2001).

tain these fluid inclusions and which originated by friction melting during earthquakes were interpreted to have formed in greenschist facies P-T conditions at depths greater than 10 km and temperatures higher than 280°C. Therefore, the pseudotachylytes and the associated fine-grained ultracataclasites cannot correspond to the Quaternary activity of the Nojima fault. These events have been interpreted to have occurred after the solidification of the granodiorite but before the deposition of the Kobe Group (Boullier *et al.*, 2001), that is some time between 80 Ma and 40 Ma. Recent dating of pseudotachylyte at 56±4 Ma using the zircon fission-track method (Murakami and Tagami, 2004) confirms our assumption and confirms previous fission-track data obtained on GSJ borehole samples indicating that the rocks around the fault have been reheated around 30–40 Ma ago, well after the initial cooling of the granodiorite to 210–310°C that occurred at 74±3 Ma (Murakami *et al.*, 2002).

Fig. 6. Textural features in laumontite veins. (a) Blocky internal structure in a fractured granodiorite at 659.45 m depth; note the fractured quartz grain (Qtz, black in the center) cemented by laumontite. Crossed polars. (b) Fine-grained hydraulic fracture containing fragments of surrounding minerals in a matrix of very fine-grained laumontite (Lau, 588.75 m depth, crossed polars). (c) Stylolite developed in the fine-grained laumontite matrix of a hydraulic fracture (586.50 m depth). The orientation of the stylolite is subvertical and parallel to the fault plane.

3.3 Hydrothermal alteration

Ohtani *et al.* (2000) and Fujimoto *et al.* (2001) distinguished three major episodes of hydrothermal alteration within the fault granodioritic wall rocks in the GSJ drill hole. These episodes are characterized successively by

Fig. 7. Textural features in carbonate veins. (a) blocky calcite (Cc) vein in a fractured and altered granodiorite (501 m depth). Note the fractured quartz grains (Qtz) and the plagioclase (Pl) entirely replaced by laumontite (Lau). (b) Very thin siderite veinlets cross-cutting a compacted cataclasite. The actual orientation of the veinlets is subvertical and parallel to the fault plane (623.50 m depth). (c) Fine-grained hydraulic fracture (black on the microphotograph) containing fragments of the surrounding cataclasite in a matrix of very fine-grained siderite and ankerite (Si+Ank, 623.50 m depth). Same sample as in Fig. 7(b).

chlorite, zeolite and then carbonates. Some clays have also been observed within the fault at Hirabayashi village (Otsuki *et al.*, 2003) and detected by X-ray diffraction in the core samples (Fujimoto *et al.*, 2001) but will not be de-

Table 1. Principal occurrences and features of the hydrothermal minerals in the GSJ drillhole.

Mineral	Chlorite	Zeolite: laumontite	Siderite	Carbonate
Stability field	ca. 300°C	ca. 150-280°C		less than 100°C
Texture	as rosettes in small cavities in cracks with albite	in veins, blocky coarse-grained filling in hydraulic fractures, with small fragments of cataclasites or minerals	in thin veinlets parallel to the flattening plane within the fault core	calcite: blocky coarse-grained veins, with scarce analcite in hydraulic fractures close to the fault core, with fragments of cataclasite or mineral (ankerite and siderite)
Alteration product	alteration of biotite and amphibole	in-situ replacement product of plagioclase		alteration product of plagioclase, biotite and amphibole
Mechanisms of formation		hydraulic fracturation	Taber growth	hydraulic fracturation
Subsequent deformation		dissolution processes: stylolites brecciation in the fault zone	brecciation	dissolution processes: stylolites and schistosity brecciation and comminution in thin fine-grained gouge zones
Suggested relative age	prior to the Kobe Group deposition	prior to the Kobe Group deposition	quiescence stage	Quaternary to recent

scribed in this study. Table 1 gives the principal occurrences and features of these hydrothermal minerals.

The structures accompanying laumontite alteration are very similar to those described by Blenkinsop and Sibson (1992) in the Cajon Pass drill hole. First, laumontite veins with straight boundaries and blocky internal structures (Bons, 2000) are observed in the whole drill hole (Fig. 6(a)). Then, hydraulic fractures occur where angular fragments of neighbouring minerals or cataclasites are embedded in a fine-grained matrix of laumontite (Fig. 6(b)). Laumontite is the main product of transformation of plagioclase and a common infill of fractures within quartz (Fig. 6(a)). Similarly, blocky calcite veins are also observed in the drill hole (Fig. 7(a)) and are clearly later than laumontite.

Within the fault zone, very thin siderite veinlets are parallel to the fault plane (Fig. 7(b)) and postdate the veins described above. They display fibrous internal structure and may have formed by “Taber-growth” (Means and Li, 2001). Above the fault core, these siderite veinlets are crosscut by hydraulic fractures showing jigsaw contours and fragments of neighbouring minerals or cataclasites in a mixture of euhedral ankerite and siderite crystals (Fig. 7(c); Boullier *et al.*, 2004). The fine-grained laumontite and carbonate veins display deformation structures such as stylolites or dissolution features (Fig. 6(c); Boullier *et al.*, 2004, figures 9 and 10).

The similarity of textures suggests that zeolites and carbonates may be attributed to comparable hydrothermal and deformation processes that occurred at different depths and temperatures. The succession (1) laumontite, (2) calcite±analcite, (3) siderite±ankerite can be deduced from thin sections observations. This mineralogical succession is consistent with decreasing temperature conditions by comparison with hydrothermal alteration parage-

neses in Cajon Pass (James and Silver, 1988; Vincent and Ehlig, 1988). The stability field of laumontite could be estimated between 150°C and 280°C depending on the pressure (Zen and Thompson, 1974). The presence of laumontite within pseudotachylyte-associated ultracataclasites has been demonstrated by X-ray diffraction (Otsuki *et al.*, 2003). All together, these observations suggest that laumontite alteration as well as friction melting should be related to the first stage of the structural evolution of the Nojima fault.

In contrast, the carbonate-filled hydraulic fractures are compatible with the composition of the fluid which is presently percolating through the fault (Sato and Takahashi, 1999) and, therefore, may have been formed during the Quaternary activity of the Nojima fault (Boullier *et al.*, 2004). The siderite veinlets which are younger than laumontite alteration but older than carbonate-filled hydraulic fractures, could have formed during the quiescent period between the two stages of deformation on the Nojima fault.

3.4 The latest events: thin fault gouge zones

The youngest structures observed in the GSJ borehole are symptomatic of two types of deformation processes: pressure solution expressed by dissolution features (stylolites, Fig. 6(c)) and brecciation/comminution expressed by thin fault gouges which are especially numerous below the fault core (i.e. in 625–635 m interval in the GSJ borehole). These two processes correspond to very low and high strain-rate mechanisms respectively and may tentatively be attributed to interseismic and seismic periods, although a controversy still exists on the seismic or aseismic character of cataclasites and gouges (see the review by Snoko and Tullis, 1998). In order to understand the deformation processes within the gouge zones (comminution, compaction, dissolution, recrystallization), the 2D grain-size distribution has been measured (Fig. 8(a)) in fault rocks using back-scattered

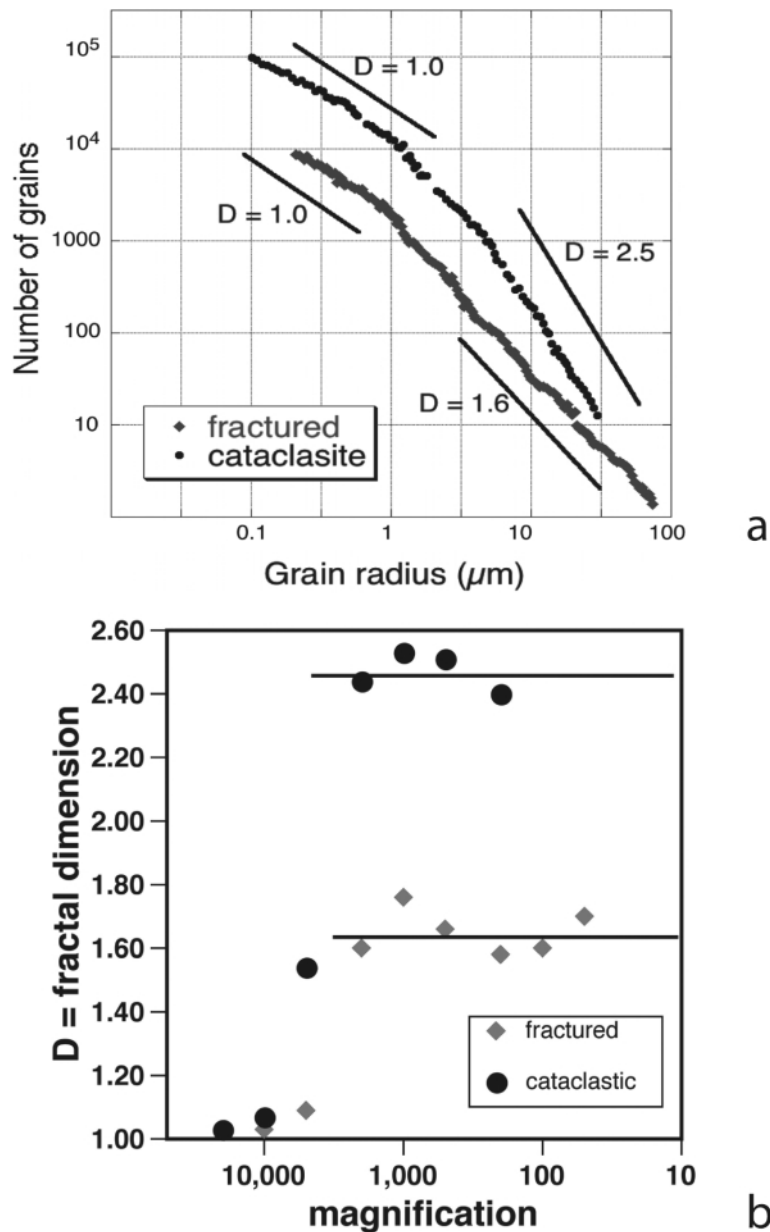

Fig. 8. (a) Grain size distribution obtained from SEM-images of thin sections of fractured rocks (522.88 m depth) and of cataclasites (624.41 m depth). The negative of the slope is the fractal dimension, D . (b) Variations of D values for fractured rocks (522.88 m depth) and cataclasites (624.41 m depth) as a function of the magnification of the images. A high magnification relates to a small grain size. The cataclasites have a higher D -value (2.5) than the fractured grains (1.6).

SEM images with different magnifications. With help of the public domain software ImageJ (<http://rsb.info.nih.gov/ij/>), grain boundary maps were drawn using a combination of automatic and manual grain boundary tracing. For automatic tracing a method similar to that described by Heilbrunner (2000) was used. The grain size in Fig. 8 is the equivalent radius of a circle having the same area as the grain. An image at $\times 100$ magnification covers an area of 11 mm². For each sample at each magnification, at least 500 grains were counted. For the grain size distribution of the rock, we have distinguished fractured fault rocks in which the fragments or counterparts could be fitted together (522.88 m depth), from the cataclasites in which counterparts cannot be identified (624.41 m depth). The grain size distribution can also be displayed as magnification of the

images versus the fractal dimension (D -value) observed in each image (Fig. 8(b)). On these figures (8(a) and 8(b)) it appears that:

- for large grain sizes (low magnifications) the D values are 1.6 for fractured rocks and 2.5 for cataclasites.
- for small grain sizes (high magnifications) the slope of the distribution approaches 1 in both cases.
- the pinning point between large and small grain sizes is close to the grinding limit (1.7 μm diameter for quartz; Prasher, 1987).
- much smaller particles than the grinding limit are observed (ca. 50 nm).

Blenkinsop (1991) has studied the grain size distribution and fractal dimension of cataclastic granitoid samples from the Cajon Pass drilling project. These granitoid cataclasites originate from various depths, up to 2807 m and have 2D fractal dimensions of 0.88–2.08. The fractal dimensions we found are higher, possibly because our samples were deformed later again during a subsequent episode, or because we analyzed more grains and studied a wider range of smaller grain sizes. Our results for the pseudotachylyte-related ultracataclasites of the Nojima fault (624.41 m depth) are comparable to the observations of Monzawa and Otsuki (2003), who studied the grain size distribution of larger grains for the Nojima and three other fault zones. We were able to measure the sizes of the very small grains with the Scanning Electron Microscope. These grains have a diameter that is much smaller than the grinding limit. Therefore, grinding is not the only effective mechanism to decrease the grain size. Abrasion or dissolution might be involved in the grain size reduction of the smallest particles. We report higher D values for cataclasites (2.5) than for fractured fault rocks (1.6) within the Nojima fault. The difference may be due to increasing strain or variations in confining pressure (Amitrano and Schmittbuhl, 2002) or to additional active processes in cataclasites such as fluidization as suggested by Monzawa and Otsuki (2003). However, more measurements are needed on different types of fault rocks in order to test the response of the grain size distributions to quiescent periods during which compaction or recrystallization mechanisms may occur as suggested by studies of experimental and naturally deformed fault rocks (Keulen *et al.*, 2003a, b).

Since they are the youngest observed deformation structures in the drill hole, the thin gouge zones are tentatively attributed to recent and near-surface seismic activity.

4. Remaining Questions and Conclusions

The Nojima fault has undergone a multistage evolution. At least two main periods can be distinguished. The first one occurred before the deposition of the Kobe Group (<40 Ma) and before the uplift of the granodioritic basement. The second (Late Pliocene to Quaternary) corresponds to the 490 to 540 m vertical offset of the unconformity at the base of the Kobe Group. Therefore, the structures observed in the drill hole can be attributed to either one or the other period.

Given our data and observations, the imprint of the first period is represented by the pseudotachylytes and a NNE-SSW compressional event expressed by shortened biotite cleavage planes and healed fluid inclusion planes. The later structures correspond to a sinistral strike-slip movement on the Nojima fault. As laumontite is stable between 150 and 280°C (Zen and Thompson, 1974), it was probably formed also prior to the deposition of the Kobe Group and, therefore, it is tentatively related to the first period. If friction melting (pseudotachylytes) and laumontite alteration were contemporaneous at ca. 56 Ma (Murakami and Tagami, 2004), it means that the temperature deduced from fluid inclusions in pseudotachylytes (>280°C, Boullier *et al.*, 2001) may have been slightly overestimated.

On the basis of similar composition between carbonate

infill and the fluid sampled in the fault after drilling, Boullier *et al.* (2004) have interpreted the carbonate-filled hydraulic fractures as due to co-seismic circulation of fluids during Quaternary or Recent activity of the fault. Consequently, the thin gouge zones being younger than the carbonate hydraulic fractures are themselves attributable to the latest period of activity of the Nojima fault.

Thickness of the fault zone (>46.5 m) is determined from alteration and deformation features (Tanaka *et al.*, 2001; Ohtani *et al.*, 2000) and most of the width of the fault is characterized by laumontite alteration (Fujimoto *et al.*, 2001). Therefore, there is no correlation between the present-day width of the fault zone and the measured vertical Quaternary (ca. 500 m) movement and this set of data should be used with caution to assess a relationship between thickness of the gouge zone and total displacement along faults (Scholtz, 1990).

Some questions remain: should we consider some quiescent intervals between the major periods of activity? If yes, what could be the textures indicative of this quiescence? Significant changes in the fluid composition percolating through the fault probably occurred between the laumontite and the carbonate episodes. Could it be correlated with a change in the origin or the main fluid reservoirs or with different circulation or mixing paths?

If it is often possible to interpret the different structures observed in the fault zone in terms of low or high strain rate processes, it is still difficult, if not impossible, to interpret them in terms of kinetics or dynamics. What is the duration of the aseismic intervals? Are all the cataclasites seismic or not? If they are seismic, what could be the corresponding earthquake magnitudes?

The evolution of the Nojima fault appears more complex than firstly expected. At least two periods of activity are suspected which are very difficult to decipher from the observation of the drill cores alone. More data are needed on the age of the laumontite or carbonate alteration stages, on the origin of the percolating fluids and on the fluid-rock exchanges. Nevertheless, and even if some questions remain, the GSJ and other drill holes through the Nojima fault represent an important opportunity to study the mechanisms of deformation in active faults and the interactions between fluids and deformation.

Acknowledgments. A.-M. Boullier thanks the organizers of the Second International Symposium on Slip and Flow Processes in and below the Seismogenic Zone for their invitation. The authors are grateful to their colleagues from Japan, France, Switzerland and elsewhere for fruitful discussions during these five years of collaboration. They acknowledge also H. Tanaka and his students for working hard for core handling and preparation of polished sections, T. Nogami and C. Nevado for making high quality thin sections. The constructive review by G. di Toro and the editorial work made by R. Norris improved the paper significantly. This study was financially supported by the CNRS and Ministère des Affaires Étrangères (PICS 1050).
